Abstract. We report on mutual proximity effects in *d*-wave superconductor/half-metal heterostructures which correspond to systems composed of high- T_c cuprates and manganite materials. In our study, proximity effects are induced by the interplay of two separate interface effects: spin-mixing (or rotation) surface scattering and spin-flip scattering. The surface spin-mixing scattering introduces spin-triplet pairing correlations in superconducting side; as a result, Andreev bound states are formed at energies within the superconducting gap. The spin-flip scattering introduces not only long range equal-spin pairing amplitudes in the half-metal, but also an exotic magnetic proximity effect extending into the superconductor.

The possibility of making heterostructures out of high- T_c cuprate superconductors and strong manganite ferromagnets like LSMO allow us to study the competition between superconducting and magnetic order where both are of equal strength. The manganites are of special interest since they have the same perovskite structure as the cuprates and e.g. $\text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ is close to totally spin polarized i.e. a half metal[1]. We report initial results from an on-going study of the electron density of states (DoS) and the induced magnetism and superconductivity in half-metal/*d*-wave superconductor/half-metal trilayers. In particular we wish to identify properties that would allow us to distinguish between a structure having the two half-metals with parallel spin-bands from a one having them anti-parallel.

The study is based on quasiclassical Green's function theory and the key issue is to pose the correct boundary conditions that connects a superconducting half-space with a half-metallic one where only one spin-band is present[2, 3, 4, 5, 6]. In order to have coherent transport between a superconductor and a half-metal the interface needs to be spin-active, i.e. to reflect or transmit quasiparticles (and quasiholes) in a manner that depends on the orientation of their spin relative to the magnetic orientation that defines the spin-active interface. There are two different ways of spin-active scattering the interface may possess that we take into account: **i)** *spin-mixing* or *spin-rotation*, the quasiparticle (quasi-hole) acquires a phase shift, $\pm\Theta_m/2$, with the sign depending its spin orientation. The presence of spin-mixing introduces Andreev states in the DoS below the gap-energy Δ and an (magnetic) exchange field in the superconductor [3, 4]. **ii)** *spin-flip scattering*, the half-metal allows trans-

mission only of one spin orientation which leads to two channels, with hopping amplitudes $\tau_{\uparrow\uparrow}$ and $\tau_{\downarrow\downarrow}$, of spin-scattering [6]. Through spin-flip scattering equal-spin superconducting correlations can be admitted into the half-metal. These two ways of spin-activeness may be accounted for by the boundary conditions the quasiclassical Greens function must obey at the superconductor/half-metal interface via the set of *phenomenological* parameters $(\Theta_m, \tau_{\uparrow\uparrow}, \tau_{\downarrow\downarrow})$ [6].

The geometry we study is that of two equal length half-metals, length L_{HM} , that sandwich a *d*-wave superconductor, length L_S . Both types of material are assumed to conduct in two-dimensional planes and the contact between them is made between these planes. Furthermore we consider either that the two half-metals are parallel, both conduct in the same spin band, or they are anti-parallel and conduct in opposite spin bands. The sizes of the systems are taken to be on the order of $10 \xi_0$ ($= \hbar v_f / 2\pi k_B T_c$, the coherence length of the superconductor) and we assume clean materials so that impurity scattering may be neglected. Finally, since we consider a *d*-wave superconductor the *ab*-plane of the superconductor may be oriented with respect to the interface normal. 5A It is well known that the *d*-wave superconductor admits zero-energy bound states (ZEBS) in the DoS if the *ab*-plane is not aligned to the interface [7]. These ZEBS will be shifted from zero energy by a finite spin-mixing scattering and the DoS of the 45°-degree rotated (or [110]) *d*-wave turns out to be very sensitive to weak spin-mixing.

In Figure 1 we display the orderparameter profile in the *d*-wave superconductor, the triplet pairing correlations (TPC) both in the superconductor and in the half-

FIGURE 1. To the left we plot the amplitude of the d-wave orderparameter as well as the triplet pairing correlations (TPC). The TPC arise from the (repeated) scattering off the spin-active interfaces and they are also induced as equal-spin TPC ($T \sum_n \langle \sin \phi f_x(x, \phi; \epsilon_n) \rangle$) in the half-metal. The interface parameters are $[\Theta_m = \frac{\pi}{4}, \tau_{\uparrow\uparrow} = \frac{0.1}{\pi}, \tau_{\downarrow\uparrow} = 0.9 \tau_{\uparrow\uparrow}]$ which corresponds to a low-transmission interface that is strongly spin-active. The full lines correspond to parallel alignment of the conduction bands of the two half-metals and dashed lines to anti-parallel alignment. In the center we show the total density of states (DoS) both in the half-metal and in the superconductor. For the superconductor we show the DoS at the interface and in the center ($x=0$). Finally to the right we show the induced exchange field in the superconductor for three values of transparency of the interface. Exchange fields $v_{x,z}$ are calculated assuming a Fermi-liquid parameter $A_0^d = -0.7$. The full (dashed) lines corresponds to (anti-)parallel half-metal alignment.

metal, and the angle averaged (total) DoS at various locations in our structure for a representative set of parameters. The temperature is set to $0.1T_c$. In addition to finite size effects, the orderparameter is strongly suppressed in the vicinity of the interface due to the sign nature of d-wave pairing function. However, its magnitude at the interfaces is slightly enhanced by the spin-mixing scattering compared to that of a d-wave superconductor at a spin-inactive interface. The spin-mixing scattering generates $S_z = 0$ TPC (f_z) in the superconductor while spin-flip scattering induces equal-spin $S_z = \pm 1$ TPC both in half-metal and in the superconductor (f_x). Although parallel or anti-parallel alignment hardly makes a difference on the magnitude of the orderparameter, the TPC in parallel and anti-parallel alignments shows symmetric or antisymmetric behavior with respect to the center, respectively. For more transparent interfaces the equal-spin TPC grow stronger and gives rise to an exchange field which direction-axis rotates in the superconductor. Typical magnitude for the exchange fields is $\sim 10\%$ of Δ_0 at the interface and decaying into the center of the superconductor. Note also that for the [110]-crystal the exchange field has the opposite symmetry with regard to the center-point compared to the TPC. For the [100]-crystal these symmetries are the same and the TPC have a $\cos \phi$ p-wave basis function compared to the $\sin \phi$ for the [110]-crystal.

To investigate the alignment effects further, we show the DoS for both cases in the center panel of Figure 1. For both half-metal alignments, the ZEBS split in to two peaks in the DoS on the superconductor side owing to the spin-mixing scattering[4]. There is also a change in the DoS in the half-metal sides via the proximity effect. This

is due to the spin-flip scattering. We find the alignment difference clearly manifested in the DoS in superconductor side. In contrast to the sharp peaks in the DoS the anti-parallel alignment shows, the bound-states peaks in parallel alignment are broadened or even split by finite size effects. This difference is due to that interference of repeated spin-mixing scattering of the bound states in parallel alignment is constructive and hence a split bound-state signature DoS. For the anti-parallel alignment this constructive interference is canceled due to that consecutive scattering picks up opposite phase kicks at either interface.
